## Abstract

The possible existence of  $\text{FN}_5$  was studied by *ab initio* electronic structure theory. Calculations were carried out at the MP2/6-31+G(d) and CCSD(T)/aug-cc-pVDZ levels of theory for the  $\text{N}_5^+\text{AsF}_6^-$  ion pair and its decomposition to  $\text{FN}_5$  and  $\text{AsF}_5$ . Six different vibrationally stable isomers of  $\text{FN}_5$  were identified. Intrinsic reaction coordinate (IRC) and dynamic reaction path (DRP) calculations were used to study the isomerization of  $\text{FN}_5$  and its decomposition to  $\text{FN}_3$  and  $\text{N}_2$ . A Rice-Ramsperger-Kassel-Marcus (RRKM) analysis was performed, indicating upper limits to the lifetimes of the  $\text{FN}_5$  isomers in the nanosecond range. These theoretical predictions were confirmed by an experimental study of the thermolyses of  $\text{N}_5\text{AsF}_6$  and  $[\text{N}_5]_2\text{SnF}_6$  and the displacement of  $\text{FN}_5$  from  $\text{N}_5\text{SbF}_6$  with  $\text{CsF}$ , using FT-IR spectroscopy. In accord with the theoretical predictions, the primary reaction product  $\text{FN}_5$  could not be observed, but its decomposition products  $\text{FN}_3$ ,  $\text{F}_2\text{N}_2$ , and  $\text{NF}_3$  were identified.

## Introduction

Polynitrogen compounds are of great interest as high energy density materials (HEDM).<sup>1-5</sup> Although theoretical studies have predicted numerous kinetically stable polynitrogen compounds,<sup>4</sup> almost all attempts to synthesize them have failed due to their very high endothermicities, low energy barriers towards decomposition, and a lack of suitable synthetic methods. The high energy content of polynitrogen compounds arises from an unusual property of nitrogen that sets it apart from most other chemical elements. Its single and double bond energies

are considerably less than one-third and two-thirds, respectively, of its triple bond energy. Therefore, the decomposition of polynitrogen species to  $N_2$  is accompanied by a large release of energy.<sup>1</sup>

Recently, the  $N_5^+$  cation has been synthesized and characterized.<sup>1,2</sup> It represents only the second known homonuclear polynitrogen species after  $N_3^+$ ,<sup>6</sup> that is stable and can be prepared on a macroscopic scale. Its bent structure of  $C_{2v}$  symmetry (Figure 1) was established by a crystal structure determination of  $N_5^+Sb_2F_{11}^-$  and vibrational and NMR spectroscopy, and is in accord with *ab initio* and density functional theory (DFT) calculations.<sup>1,2,7</sup> The bent structure avoids the unfavorable neighboring positive charges that would result from a linear structure.<sup>1</sup>

Most salts consisting of an  $X^+$  cation and a complex fluoro anion,  $MF_6^-$ , are prepared by the transfer of an F anion from the parent FX molecule to the strong Lewis acid  $MF_5$  (eq. 1).

Usually this reaction is reversible and the FX molecule can be regenerated by either thermolysis of  $X^+MF_6^-$  or a displacement reaction between  $X^+MF_6^-$  and a stronger Lewis base, such as CsF (eq. 2).

Only a few  $X^+MF_6^-$  salts are known for which FX cannot be generated in this manner. Typical examples are the  $NF_4^+$ ,<sup>8</sup>  $ClF_6^+$ ,<sup>9</sup> and  $BrF_6^{+10}$  salts where the corresponding FX parent compounds cannot exist because the maximum coordination number of the central atom would be exceeded.<sup>11</sup> The reverse case, where an amphoteric FX molecule exists but the corresponding  $X^+$  cation does not, is also known but rare. A typical example is  $FN_3$  that does not form a stable  $N_3^+$  salt with strong Lewis acids.<sup>12</sup>

The availability of several marginally stable  $N_5^+$  salts, such as  $N_5^+AsF_6^-$ ,<sup>1</sup>  $N_5^+SbF_6^-$ ,<sup>2</sup> and  $[N_5]^+_2[SnF_6]^{2-}$ <sup>13</sup> that can be readily subjected to thermolysis or displacement reactions, offered an ideal opportunity to probe the possible existence of the unknown  $FN_5$  molecule. While carrying out the theoretical study, we have also investigated the potential energy surfaces of the  $N_5^+AsF_6^-$  ion pair and its  $FN_5$  decomposition product in order to better understand the likely structure and stability of this new polynitrogen species.

## Experimental Section

*Caution! Reactions of  $N_5^+$  salts can be violent and can result in explosions,<sup>1,2</sup> particularly when highly shock sensitive  $FN_3$ <sup>12,14</sup> is formed as a decomposition product. Therefore, these materials should be handled only on a small scale with appropriate safety precautions (face shield, leather gloves, and protective clothing).*

**Materials and Apparatus.** All reactions were carried out in a demountable Teflon-PFA condensing side arm of a 5 cm path length, Teflon-FEP infrared cell equipped with AgCl windows. Nonvolatile solids were loaded in the dry nitrogen atmosphere of a glove box into the side arm of the IR cell. The cell was then evacuated and placed into the FT-IR spectrometer. The decomposition or displacement reactions were initiated by gentle warming, and the volatile decomposition products were continuously monitored by infrared spectroscopy using a Mattson Galaxy FT-IR spectrometer. Volatile materials were handled on a stainless steel/Teflon-FEP vacuum line.<sup>15</sup>

The  $N_5^+AsF_6^-$ ,<sup>1</sup>  $N_5^+SbF_6^-$ ,<sup>2</sup> and  $[N_5]^+_2[SnF_6]^{2-}$ <sup>13</sup> starting materials were prepared by literature methods. The CsF (KBI) was fused in a platinum crucible, transferred while hot into the dry box, and finely powdered.

## Computational Methods

Initial optimizations of all structures were performed using second order perturbation theory (MP2)<sup>16</sup> and the 6-31+G(d) basis set.<sup>17</sup> Hessians (energy second derivatives) were calculated for the final equilibrium structures to determine if they are minima (positive definite hessian) or transition states (one negative eigenvalue). At the final MP2/6-31+G(d) geometries, improved relative energies were obtained using singles and doubles coupled cluster theory with triples included perturbatively (CCSD(T))<sup>18</sup> and the aug-cc-pVDZ basis set.<sup>19</sup> The MP2 calculations were performed using the electronic structure code GAMESS,<sup>20</sup> while the CCSD(T) calculations were carried out using ACES II.<sup>21</sup>

Intrinsic reaction coordinate (IRC) pathways<sup>22</sup> were employed in the study of the  $FN_3$  species in order to connect isomer minima, transition states, and decomposition products. The IRC method is the minimum energy path (MEP) in mass weighted Cartesian coordinates. IRC calculations were performed with GAMESS using the second-order method developed by

Gonzalez and Schlegel<sup>23</sup> with a step size of 0.1 (amu)<sup>1/2</sup>-bohr.

A simple Rice-Ramsperger-Kassel-Marcus (RRKM) analysis was performed on the isomers included in the potential energy surfaces obtained with the IRC calculations. The RRKM theory of reaction dynamics can be used to give an upper limit to the lifetime of the minima.<sup>24</sup> It assumes a microcanonical equilibrium and a locally separable reaction coordinate. The microscopic rate constant is proportional to the sum of states of the  $i^{\text{th}}$  reaction channel ( $W_N^i(E - E_0^i)$ ) divided by the reaction density of states ( $\rho_N(E)$ ):

$$k \propto W_N^i(E - E_0^i) / \rho_N(E) \quad (3)$$

$$k = \frac{\prod_{i=1}^{3N-6} \nu_i}{\prod_{i=1}^{3N-7} \nu_i^{\text{TS}}} \left( \frac{E - E_0^{\text{barrier}}}{E} \right)^{3N-7} \quad (4)$$

where  $k$  = rate constant

$\nu_i$  =  $i^{\text{th}}$  frequency of the minima

$\nu_i^{\text{TS}}$  =  $i^{\text{th}}$  frequency of the transition state

$E$  = applied energy

$E_0^{\text{barrier}}$  = barrier energy

Note that the lifetime  $\tau = 1 / k$ .

Finally, in order to further study the decomposition and stability of several  $\text{FN}_5$  isomers, the dynamic reaction path (DRP) method was used to add photons (kinetic energy (KE)) to one or more  $\text{FN}_5$  vibrational normal modes.<sup>25</sup> The DRP method, a classical trajectory approach, is based on a quantum chemical potential energy surface (PES) that need not be known ahead of time. Unlike the IRC, energy is strictly conserved along the dynamic reaction path. Thus, larger step sizes can be used. In this way a classical trajectory is developed "on-the-fly" without prior knowledge of the PES. GAMESS can use normal modes as the initial dynamic reaction coordinates. An initial KE and velocity direction is supplied to one or more modes (in units of quanta).<sup>26</sup> The strategy is to provide energy to those modes that appear to lead to desired reaction

products. Because there is often significant mode-mode mixing, the applied energy is usually in excess of the reaction/decomposition barrier. This is a direct dynamics method in that the *ab initio* (in the present case, MP2) gradients/forces are calculated at each step and are then used to solve Newton's equations of motion and propagate the system. Step sizes ranged from 0.1 to 0.2 fs, depending on how well energy conservation criteria were satisfied.

## Results and Discussion

**The  $N_5^+AsF_6^-$  Ion Pair.** The starting points for the calculations were the  $AsF_6^-$  and  $N_5^+$  ions separated by a distance of  $\sim 10.0$  Å, in  $C_1$  symmetry, followed by a complete geometry optimization. The resulting ion pair is shown in Figure 2a. At the MP2/6-31+G(d) level of theory, the ion pair is 98.8 kcal/mol lower in energy than the separated ions (Table 1).

MP2 Mulliken charges on the  $N_5^+$  and  $AsF_6^-$  units within the ion pair show that the charge separation is  $\pm 0.825$ ; thus, there is relatively little charge transfer between the ions. In comparison with the separated ions (Figures 2b and 3b), the  $N_5^+$  unit in the ion pair has a less negative charge on the central N by approximately 0.3, while the terminal N atoms are about 0.2 less positive than in the isolated  $N_5^+$  ion. In the case of  $AsF_6^-$  in the ion pair, all As-F bonds except for the bond opposite to the  $N_5^+$  unit have been elongated by about 0.085 Å (Table 2). This effect can be explained by the partial removal of an electron from bonding orbitals. It is interesting to note that the bond distances in  $N_5^+$  do not exhibit a similar effect and are essentially unchanged.

In isolated  $N_5^+$ , the central N has a large negative charge (Figure 3b). This charge is reduced by a factor of two in the ion pair. All other N atoms are positive, with the terminal N atoms being most positive. This type of charge distribution can be rationalized by the valence bond structures<sup>1,2,27</sup> given in Figure 1. It must be kept in mind, however, that the magnitude of the charges varies strongly with the calculation method, although their signs and relative order remain the same. Thus, at the NBO (B3LYP/aug-cc-pVDZ) level of theory, the charges on N1, N2, and N3 are significantly smaller and amount to 0.33, 0.22, and  $-0.11$ , respectively.<sup>28</sup>

As can be seen from Figure 2a, the closest N-F distances in the ion pair are  $N2-F8 = 2.26$  Å and  $N4-F8 = 2.34$  Å. They are much longer than a typical N-F bond ( $\sim 1.3$  Å)<sup>29</sup>, but significantly

shorter than the sum of their Van der Waals radii ( $3.0 \text{ \AA}$ )<sup>30</sup> and the shortest N...F contacts observed in the crystal structure of  $\text{N}_5^+\text{Sb}_2\text{F}_{11}^-$  ( $2.72$  and  $2.78 \text{ \AA}$ ).<sup>2</sup>

Since there is still a large charge separation between the components of the ion pair, it is of interest to consider how much energy would be required to transfer  $\text{F}^-$  from  $\text{AsF}_6^-$  to  $\text{N}_5^+$  to make gaseous  $\text{AsF}_5$  and  $\text{FN}_5$ . At the MP2/6-31+G(d) level of theory, the ion pair is  $46.5 \text{ kcal/mol}$  lower in energy than the separated  $\text{AsF}_5$  and *bifurcated(bif)*- $\text{FN}_5$  molecules, indicating that it takes at least this much energy to transfer  $\text{F}^-$  from  $\text{AsF}_6^-$  to  $\text{N}_5^+$  to make *bif*- $\text{FN}_5$  and  $\text{AsF}_5$  (Figure 4). Thus, the ion pair is reasonably stable to dissociation to gaseous  $\text{AsF}_5$  and *bif*- $\text{FN}_5$ . Because an ion pair is only a poor approximation to a crystalline solid, the  $25.5 \text{ kcal/mol}$  difference between the lattice energy of  $\text{N}_5^+\text{AsF}_6^-$  ( $124 \pm 4 \text{ kcal/mol}$ )<sup>31</sup> and the ion pair energy ( $98.8 \text{ kcal/mol}$ ) must be added to the above minimum decomposition energy barrier of  $46.5 \text{ kcal/mol}$  when considering the thermal stability of solid  $\text{N}_5\text{AsF}_6$ . The resulting minimum decomposition energy barrier of  $72.0 \text{ kcal/mol}$  for crystalline  $\text{N}_5\text{AsF}_6$  is in accord with the experimental observation that this salt is marginally stable at room temperature.<sup>1</sup> The experimentally observed irreversible decomposition of  $\text{N}_5\text{AsF}_6$  at higher temperatures<sup>1</sup> is due to the subsequent rapid, highly exothermic, and irreversible decompositions of  $\text{FN}_5$  and  $\text{FN}_3$  (see below).

In addition to the  $[\text{AsF}_6][\text{N}_5]^+$  structure discussed above, a geometry search revealed a second, lower energy isomer. This  $\text{C}_{2v}$  structure is obtained from the structure shown in Figure 2a by rotating the  $[\text{AsF}_6]^-$  anion so that the  $\text{As}_6$ ,  $\text{F}_7$ , and  $\text{F}_8$  atoms are coplanar with  $[\text{N}_5]^+$ . The  $\text{C}_2$  rotation axis then passes through atoms  $\text{N}_3$  and  $\text{As}_6$ . The second symmetry plane contains  $\text{N}_3$ ,  $\text{As}_6$ , and  $\text{F}_9\text{-F}_{12}$  with  $\text{F}_9$  and  $\text{F}_{11}$  pointing towards the  $[\text{N}_5]^+$  cation and  $\text{F}_{10}$  and  $\text{F}_{12}$  pointed away from it. Some of the distinguishing features of this  $\text{C}_{2v}$  geometry are the As-F distances ( $\text{As-F}_{7,8} = 1.75 \text{ \AA}$ ;  $\text{As-F}_{9,11} = 1.81 \text{ \AA}$ ;  $\text{As-F}_{10,12} = 1.72 \text{ \AA}$ ); the  $\text{N}_1\text{-F}_8$  ( $\text{N}_5\text{-F}_7$ ) distance is  $2.80 \text{ \AA}$ . The  $\text{F}_9\text{-N}_2$ ,  $\text{F}_9\text{-N}_4$ ,  $\text{F}_{11}\text{-N}_2$ , and  $\text{F}_{11}\text{-N}_4$  distances are each  $2.47 \text{ \AA}$ . The geometry of the  $[\text{N}_5]^+$  cation is virtually identical to that in Figure 2a. This second bifurcated isomer is  $\sim 10 \text{ kcal/mol}$  lower in energy than the structure shown in Figure 2a, most likely because of the electrostatic interactions between four F atoms with N. However, the higher energy structure is more likely to yield the neutral species  $\text{AsF}_5 + \text{FN}_5$ . In either case, the ion complex is clearly much lower in energy than the separated neutrals.

**FN<sub>5</sub> Isomers.** Because the F<sup>-</sup> ion can attach itself in different ways to the three different nitrogen atoms of N<sub>5</sub><sup>+</sup>, it is necessary to explore the different possible isomers of FN<sub>5</sub> and their relative energies and stabilities. An exhaustive study was performed and six stable isomers were found. Their relevant energies and geometries are listed in Tables 3 and 4, respectively. Optimized structures were obtained for each isomer and Hessians confirmed that these structures are minima on the potential energy surface. The relevant geometrical features are summarized in Figure 5 and Table 4. The N-F and N-N bond lengths are similar for all isomers except for the bifurcated isomer (1) and the cyclic structure (6). All isomers are planar molecules. Both MP2 and CCSD(T) calculations predict the *cis*- and *cyclic*-isomers to be among the lowest energy species. Indeed, except for the bifurcated isomer, the two levels of theory predict similar relative energies (Table 3). Note that the MP2 results are not very basis set dependent. The *cis*-, *trans*-, *wag*-, and *harp*-isomers are all within a few kcal/mol of each other and can be easily interconverted by simple rotations around the N3-N4 and N4-N5 bonds. The more accurate and reliable CCSD(T) method places the bifurcated isomer 3-11 kcal/mol above the other isomers. Since the two N-F distances in this “bifurcated” isomer differ by 0.342 Å, this isomer might reasonably be described as an N<sub>β</sub>-bonded isomer with a weak secondary interaction to the other N<sub>β</sub> atom, while the other four non-cyclic isomers are all N<sub>α</sub>-bonded. The formation of the cyclic isomer (6) is less likely to form in the experiments because it would probably involve a fluoride attacking N<sub>5</sub><sup>+</sup> from the backside at its central N<sub>γ</sub> atom. Such an approach is not likely since both reacting atoms apparently carry partial negative charges that should repel each other.

Because N<sub>2</sub> is so stable, the dissociation of FN<sub>5</sub> to FN<sub>3</sub> and N<sub>2</sub> is 45.5 kcal/mol exothermic at the CCSD(T) level of theory (Table 3) and is irreversible. Therefore, it is important to explore the possible decomposition pathways for the preferred FN<sub>5</sub> isomers and to determine their energy barriers towards decomposition.

In order to explore both the isomerization and decomposition pathways, IRC studies were performed at the MP2 level of theory to connect minima with the corresponding transition states (TS). Transition states are illustrated in Figure 6, and FN<sub>3</sub> is depicted in Figure 7; detailed geometries are given in Table 5. The first IRC was started from the “bifurcated” isomer, which most closely resembles the original ion pair. Structurally, the isomer that most naturally connects with the *bifurcated*-isomer is the *harp*-isomer, since this simply requires F to move to a neighboring nitrogen atom of the N<sub>5</sub> moiety via TS14. Starting from *harp*, two PESs have been

identified (Figure 8) that the *harp*-isomer can take to reach decomposition products: a "direct" decomposition route (through TS4p) or an isomerization via the *cis*-isomer (through TS42). The *cis*-isomer decomposes directly to  $\text{FN}_3 + \text{N}_2$  (through TS2p). As shown in Figure 8 and Table 6, the bottleneck for both reaction paths is the initial barrier towards isomerization from *bifurcated* to *harp* (through TS 14), predicted to be 8.9 kcal/mol. The subsequent activation energies are much smaller, so once the *harp*-isomer is reached, the decomposition to  $\text{FN}_3 + \text{N}_2$  should proceed even more easily.

The two PESs are qualitatively similar at the MP2/6-31+G(d) and CCSD(T)/aug-cc-pVDZ levels of theory. The MP2 activation energies are larger than those from CCSD(T), and all transition states and minima, excluding the initial bifurcated species, are higher in energy than the reference *cis*-isomer. CCSD(T) predicts that all minima and TSs are higher in energy than the reference *cis*-isomer (Table 3).

The results of a *qualitative* RRKM analysis (using the vibrational frequencies in Table 7) for the two isomerization reactions and two decomposition reactions are shown in Tables 8 and 9. Several values were chosen for  $E$ , the applied energy, in equation (4) for each minimum. Since the CCSD(T) and MP2 activation energies are different (Table 6), a given value of  $E$  corresponds to different excess energies above the barrier. So, in Tables 8 and 9, a given amount of energy above a barrier corresponds to different values of  $E$ . Since the CCSD(T) energies were obtained as single energy calculations at the MP2 geometries, the frequencies used in both sets of RRKM calculations are those obtained from MP2. Thus, the CCSD(T) results are only qualitative, but these frequencies are not expected to be very different. Since the CCSD(T) barriers are much lower in energy than those based on MP2, the corresponding lifetimes will be smaller. Of course, the shorter the predicted lifetime, the more likely it is that the isomerization or dissociation will occur. At the CCSD(T) level of theory, the predicted lifetimes for the two isomerization reactions, *bifurcated* (1)  $\rightarrow$  *harp* (4) and *harp* (4)  $\rightarrow$  *cis* (2), are on the order of a few nanoseconds even in the case where an energy that is only 5 kcal/mol above the barrier is added. When this excess energy rises to 40 kcal/mol, these lifetimes decrease to 1-2 picoseconds. The lifetimes for the decomposition reactions, from *harp* and *cis* to  $\text{FN}_3$  and  $\text{N}_2$ , are even shorter.

**DRP Calculations.** In order to further study the decomposition and stability of the *harp*- and *cis*- $\text{FN}_5$  isomers, the dynamic reaction path (DRP) method<sup>25,26</sup> was used to provide kinetic energy to one or more vibrational normal modes.

For the *cis*-isomer, mode 10 (Figure 9a) is a good candidate for breaking the N3-N4 bond since  $\nu_{10}$  is the symmetric N3-N4-N5 stretching mode. At the MP2/6-31+G(d) level, the barrier for the decomposition,  $\text{cis-FN}_5 \rightarrow \text{FN}_3 + \text{N}_2$ , is approximately 22 kcal/mol. With the addition of approximately 35 kcal/mol to this mode, the N3-N4 bond undergoes only oscillations, and at least 51 kcal/mol of KE must be applied to this mode in order to break the N3-N4 bond (the bond breaks after 5.6 fs into such a trajectory run). Figures 10 and 11 show various structures along the trajectories with the addition of 35 and 51 kcal/mol of KE, respectively. Further illustration of this phenomenon is shown in Figure 12 where the coordinate changes in terms of the normal modes of the equilibrium structure for both  $E = 35$  and  $E = 51$  kcal/mol are plotted. With the addition of 35 kcal/mol, the KE is quickly redistributed to other modes. This dissipates the applied energy, so bond oscillations due to the activation of other modes result. For  $E = 51$  kcal/mol, the energy remains localized in mode 10; the modes become well separated and do not undergo wild oscillations. There is enough energy available to "push" the  $\text{N}_2$  fragment away so it is not recaptured during oscillations.

As noted earlier, the *harp*-isomer can decompose in a direct or stepwise manner. The MP2/6-31+G(d) barrier to direct decomposition is 7.5 kcal/mol, while the barrier for the isomerization,  $\text{harp} \rightarrow \text{cis}$ , is 5.4 kcal/mol. In the analysis of this structure,  $\nu_{12}$  (Figure 9b) appears to be a good candidate for N3-N4 bond breaking since  $\nu_{12}$  is the N4-N5 stretching mode. After the addition of 44 kcal/mol, the N3-N4 bond breaks, but it then reforms and oscillates. As in the case for the *cis*-isomer, this can be seen in the graphs of normal mode coordinate change versus time. Figure 13 shows that the energy applied to  $\nu_{12}$  dissipates to other modes even more rapidly than in the case of the *cis*-isomer.

The MP2 and CCSD(T) RRKM analyses for the addition of energy, corresponding to this DRP for both the *cis*- and *harp*-isomers, are given in Table 9. The examples discussed above are in boldface in Table 9. Consider the decomposition of the *cis*-isomer, using  $\nu_{10}$ . At least seven (four) vibrational quanta are required to surmount the barrier in this mode for MP2 (CCSD(T)), corresponding to lifetimes of 0.2 and 855 milliseconds, respectively. For an  $E$  value of 35 kcal/mol, corresponding to 10 vibrational quanta, the lifetimes are 216 and 0.9 ps, respectively.

The trajectory with  $E = 35$  kcal/mol was only run for  $\sim 0.15$  ps, and only bond oscillations were observed. For  $E = 52$  kcal/mol (15 quanta), the predicted lifetimes 116 fs and 1.7 ps for CCSD(T) and MP2, respectively. The  $E = 52$  kcal/mol trajectory shows complete bond dissociation after  $\sim 6$  fs (0.006 ps). For the *harp*-isomer, the addition of  $E = 44$  kcal/mol to mode 12 (7 quanta) shows no dissociation after  $\sim 600$  fs (0.6 ps). Upper limit lifetimes for this isomer, depending on whether one is considering the isomerization or decomposition channel, are  $\sim 3$  ps and 0.3 ps, respectively, at the MP2 level and 1.9 ps and 50.4 fs, respectively, at the CCSD(T) level. It is important to reiterate here the following point: the reason that the amount of energy required to cause dissociation in the DRP trajectories exceeds the calculated barrier heights is that the energy provided to a specific vibrational mode does not localize in the bond that breaks in the reaction.

**Experimental Results.** The vacuum thermolyses of  $N_5^+AsF_6^-$  (eq. 5) and  $[N_5]^+[SnF_6]^{2-}$  (eq. 6), and the displacement reaction between  $CsF$  and  $N_5^+SbF_6^-$  (eq. 7) were studied experimentally by fast, *in situ* FT-IR spectroscopy of the gaseous reaction products.

In excellent agreement with the above theoretical lifetime predictions for  $FN_5$ , this molecule could not be observed directly; however its expected decomposition products (eq. 8-11) were observed.

Because reactions 8-11 are all strongly exothermic, the thermodynamically most stable products,  $NF_3$  and  $N_2$ ,<sup>32</sup> were obtained as the major final products. However, the formation of smaller amounts of  $FN_3$  and  $F_2N_2$  was also observed, thus confirming the above sequence of reactions.

## Conclusions

In contrast to  $\text{FN}_3$  that can be isolated at room temperature but does not form stable  $\text{N}_3^+$  salts with strong Lewis acids,<sup>12</sup>  $\text{N}_5^+$  salts are stable but their  $\text{FN}_5$  parent molecule has very limited kinetic stability. Because of the general difficulty of correctly modeling infinite crystal lattices,<sup>33</sup> the ion pair  $\text{N}_5^+\text{AsF}_6^-$  and its dissociation products were studied. It is shown that at the MP2/6-31+G(d) level the ion pair and crystalline  $\text{N}_5^+\text{AsF}_6^-$  are more stable than the free  $\text{FN}_5$  and  $\text{AsF}_5$  molecules by 46.5 and 72.0 kcal/mol, respectively. These values represent minimum dissociation energy barriers; the latter value is in accord with the observed marginal stability of crystalline  $\text{N}_5^+\text{AsF}_6^-$  at room temperature. The  $\text{FN}_5$  molecule can exist as at least six different, vibrationally stable isomers (one cyclic, one bifurcated, and four chain-like structures) that differ in energy by only 6.4, 9.0, and 11.2 kcal/mol at the MP2/6-31+G(d), MP2/aug-cc-pVDZ, and CCSD(T)/aug-cc-pVDZ levels, respectively. Decomposition studies of  $\text{FN}_5$  reveal two distinct pathways to  $\text{FN}_3 + \text{N}_2$ . The energy change from the initial bifurcated  $\text{FN}_5$  isomer to  $\text{FN}_3 + \text{N}_2$  is predicted to be 56.0 kcal/mol at the CCSD(T) level of theory.

IRC, DRP, and RRKM calculations suggest that the energy barriers for these decomposition pathways are very low resulting in predicted life times for  $\text{FN}_5$  at room temperature on the order of nanoseconds. These predictions of an extremely short lived  $\text{FN}_5$  are confirmed by our experimental FT-IR studies on the thermolyses of  $\text{N}_5^+\text{AsF}_6^-$  and  $[\text{N}_5]^+[\text{SnF}_6]^-$ , and the displacement reaction between  $\text{CsF}$  and  $\text{N}_5^+\text{SbF}_6^-$  which showed only the expected decomposition products  $\text{FN}_3$ ,  $\text{F}_2\text{N}_2$ , and  $\text{NF}_3$ , but no evidence for the intermediate  $\text{FN}_5$ .
